Abstract

Performing lattice simulations of the four dimensional $SU(2)$ gluodynamics we find evidence for existence of three-dimensional domains whose total volume scales in physical units. Technically, the domains are defined in terms of the minimal density of negative links in $Z(2)$ projection of gauge fields. The volume can be viewed also as the minimal volume bound by the center vortices. We argue that the three-dimensional domains are closely related to confinement.

1. It is a general trend in modern theoretical physics to consider extended objects, like strings and membranes. Usually, one applies these ideas to hypothetical, high-dimensional completions of the four-dimensional world. However, lower-dimensional structures might also exist in four dimensions. At present time there is no well developed theory which would predict such structures. However, there is accumulating evidence obtained within the lattice QCD that there are lower dimensions objects percolating through the vacuum of four dimensional Yang-Mills theories. We have in mind in particular monopoles and P-vortices, for review see, e.g., [1, 2]. The length of the percolating monopole cluster L_{perc} scales in physical units [3]:

$$L_{perc} \approx (30.8)\ (fm)^{-3} \cdot V_4\,; \tag{1}$$

where V_4 is the volume of the lattice. Similarly, the area of the P-vortices scales in the physical units [4]:

$$A_{vort} \approx 24(fm)^{-2} \cdot V_4\ . \tag{2}$$

Scaling laws (1), (2) have been known since some time [1, 2] but were not originally interpreted as an evidence for existence of structures of lower dimensions. The reason is that mostly monopoles and vortices were thought of as being 'bulky' field configurations with typical sizes of order Λ_{QCD}^{-1}. It is only rather recently that it was recognized that at least at presently available lattices they do look actually as infinitely thin trajectories and surfaces, i.e. represent physical structures of lower dimensions. The basic observation which leads to this conclusion is that the monopoles and vortices are distinguished by ultraviolet divergent action, see in particular [4, 5]. In view of this there arises a highly non-trivial question on the consistency of the observations with the asymptotic freedom at short distances. The data appear to be consistent with the asymptotic freedom [6].

There is no regular way to search for lower-dimensional defects in the vacuum state of a lattice gluodynamics. Historically, the monopoles and P-vortices are singled out since they emerged as candidates for confining field configurations. Both monopoles and P-vortices are defined in terms of projected fields. In case of the monopoles one uses Maximal Abelian projection while in case of P-vortices one projects the original $SU(2)$ fields onto the closest $Z(2)$ gauge field configuration. The use of a projection makes theoretical analysis on the fundamental level difficult. Results (1), (2) are empirical observations.

In this paper we are looking for possible defects using negative links as the scanning means. Namely, we use first a $Z(2)$ projection and then minimize the number of the negative links by the residual $Z(2)$ gauge transformations. The motivation for such a procedure as well as first encouraging results can be found in [7]. In brief, negative links correspond to large potentials, $A \sim 1/a$ in the continuum limit. Minimizing potentials, on the other hand, might result in gauge invariant quantities, for a related discussion see [8].

We find, indeed, that the negative links, after minimization, occupy a part of the lattice which scales as a 3d volume in physical units:

$$V_3 \approx 2(fm)^{-1} \cdot V_4\ . \tag{3}$$

To check the projection (in)dependence we perform measurements both in the Direct- and Indirect-Maximal Center Projections (DMCP and IMCP). The details

of calculations are given in the Appendix. As a result of $SU(2) \to Z(2)$ projection, the original $SU(2)$ field configurations get projected into the closest configuration of $Z(2)$ gauge fields. The remaining $Z(2)$ gauge freedom is then fixed by maximizing the functional

$$F(Z) = \sum_{x,\mu} Z_{x,\mu} \tag{4}$$

with respect to $Z(2)$ gauge transformations ($Z_{x,\mu} \to z_x \, Z_{x,\mu} \, z_{x+\hat{\mu}}$, $z_x = \pm 1$). In analogy with the lattice $U(1)$ Landau gauge fixing the maximization of the functional (4) is called $Z(2)$ Landau gauge fixing.

2. Our results for the minimized density of the negative links are shown in Fig. 1. As is seen from the data, both in case of IMCP and in case of DMCP the density of negative links is proportional to the lattice spacing.

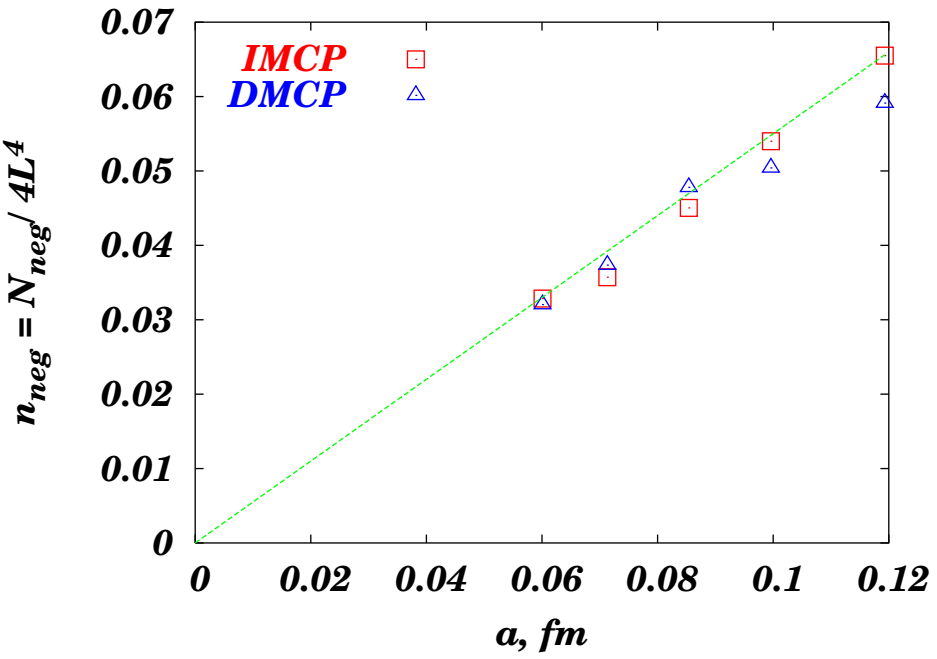

Figure 1: Probability for a link to be negative in $Z(2)$ gauge field configuration after $Z(2)$ Landau gauge fixing.

Let us emphasize that this does imply that there is a strong correlation between the negative links and they are accumulating within three-dimensional volumes. Indeed, plaquettes dual to P-vortices do have negative links by definition. Thus, if we had isolated negative links, then their number would be less than the number of negative plaquettes (six negative plaquettes correspond to each isolated link). The data indicate, on the other hand, that the number of negative links is larger than the number of the negative plaquettes. This could be interpreted only as indication that there are many plaquettes with two or four negative links so that they do not contribute to the density of the P-vortices but do contribute to density of the negative links. The negative link is dual to a 3d elementary cube, the collection of these cubes form a 3d volumes which is bound by P-vortices (which also belong

to the dual lattice). The $Z(2)$ Landau gauge corresponds to minimization of the volumes spanned on $Z(2)$ gauge invariant P-vortices. Thus, it appears that there exists a three dimensional volume on the dual lattice whose volume scales in the physical units, the fit of the data of Fig. 1 gives (3).

3. Let us mention again that the action associated with the vortices and monopoles is ultraviolet divergent [4, 5]:

$$S_{vort} \approx 0.53 \frac{A_{vort}}{a^2} \ , \ S_{mon} \approx \ln 7 \frac{L_{perc}}{a} \ , \tag{5}$$

where $S_{vort} = \beta(1 - \frac{1}{2} < \mathrm{Tr} U_P^{vort} >)$ is measured on the plaquettes U_P^{vort} dual to P-vortices. The action $S_{mon} = \beta(1 - \frac{1}{2} < \mathrm{Tr} U_P^{mon} >)$ is measured on the plaquettes nearest to monopole currents. From the theoretical point of view it is crucial that (5) is consistent with the asymptotic freedom [6].

However the ultraviolet divergence of the action on the plaquettes belonging to the $3d$ volume would contradict QCD (for a related discussion see [6]). We have measured this action, S_{3d}, and found that, indeed,

$$< S_{3d} > \ - \ < S >_{lattice}^{withoutPV} \approx 0 \ , \tag{6}$$

in agreement with theoretical expectations.

4. Now, we will argue that the 3d volumes discussed above might be relevant to the mechanism of the confinement. Indeed, let us remind the reader procedure introduced in Ref. [9]. One determines $Z_{x,\mu}$ variables (see, e.g., the Appendix below) and then replaces the original link variables $U_{x,\mu}$ by new matrices $\tilde{U}_{x,\mu}$ defined as

$$\tilde{U}_{x,\mu} \equiv U_{x\mu} \cdot Z_{x,\mu} \ , \tag{7}$$

where the Z factors are ± 1. A remarkable observation of Ref. [9] is that the string tension evaluated by using $\tilde{U}_\mu$ matrices vanishes and there is no confinement for the modified vacuum.

Usually this procedure is dubbed as 'removal' of the P-vortices. Note, however, that the total area of vortices scales in physical units and in this sense they represent d=2 defects. Moreover, the Wilson line is obviously a d=1 subspace. Thus, in d=4 the subspaces d=1 and d=2 do not intersect at all, generally speaking. For a local change (like (7)) to affect the Wilson line one should change fields at least on a d=3 subspace. Thus, no local change of the plaquettes belonging to the vortices can eliminate confinement. The resolution of the paradox is that the field modification (7) affects originally links, not plaquettes directly.

Thus, one can ask what is the minimal number of links which are to be changed to eliminate confinement through the procedure (7). In this way we come back to the 3d volume considered in the bulk of the paper. Moreover, on average the number of intersections of a Wilson line with the d=3 volume is given by (see Fig. 1 and eq. (3)):

$$\langle N_{intersection} \rangle \approx 0.5 \frac{P_W}{fm} \ , \tag{8}$$

where P_W is the perimeter of the Wilson line. Note that the number of the intersections (8) does not depend on the lattice spacing a.

It is worth emphasizing that if one chooses randomly links where the sign of the matrix $U_{x,\mu}$ is changed then the area law cannot be affected and only extra dependence of the Wilson loop on the perimeter could be generated. Thus, elimination of the confinement through multiplication of the Wilson loop by $(-1)^{N_{intersection}}$ is possible only in case of a coherent effect. In this context, one can claim these 3d defects to be responsible for the confinement.

Of course the above discussion does not rule interpretation a la Bohm-Aharonov effect (which is related to the linking number of the surface with magnetic flux and the Wilson line in 4d space [11]). Indeed, it is not possible to eliminate 3d volumes without eliminating their boundary, the P-vortices. Moreover the modified Wilson loop $W' = \mathrm{Tr}\prod_{l\in C}\{U'_l\}$ can be expressed through the initial Wilson loop, W, as:

$$W' \;=\; \exp\{i\pi\mathcal{L}(\mathcal{P},\mathcal{C})\}\; W\,, \tag{9}$$

here $\mathcal{L}$ is the 4d linking number of the surface of the P-vortex, $\mathcal{P}$, and the Wilson contour $\mathcal{C}$. $\mathcal{L}$ can be expressed as the number of intersections of $\mathcal{C}$ with the 3d volumes, or as the integral over $\mathcal{P}$ and $\mathcal{C}$.

Finally let us note that recently 3d manifolds corresponding to the topological charge density of the definite sign were found [10] in 4d lattice $SU(2)$ gauge theory.

Appendix

We perform our calculations both in the Direct [12] – and the Indirect [13] – Maximal Center Projections (DMCP and IMCP). The DMCP in SU(2) lattice gauge theory is defined by maximization of the functional

$$F_1(U) = \sum_{x,\mu} \left(\mathrm{Tr}U_{x,\mu}\right)^2\,, \tag{10}$$

with respect to gauge transformations, $U_{x,\mu}$ is the lattice gauge field. Maximization of (10) fixes the gauge up to Z(2) gauge transformations and the corresponding Z(2) gauge field is defined as: $Z_{x,\mu} = \mathrm{signTr}U_{x,\mu}$. To get IMCP we first fix the maximally Abelian gauge maximizing the functional

$$F_2(U) = \sum_{x,\mu} \mathrm{Tr}\left(U_{x,\mu}\sigma_3 U^+_{x,\mu}\sigma_3\right)\,, \tag{11}$$

with respect to gauge transformations. We project gauge degrees of freedom $U(1) \to Z(2)$ by the procedure completely analogous to the DMCP case, that is we maximize $F_1(U)$ (10) with respect to $U(1)$ gauge transformations.

To fix the maximally Abelian and direct maximal center gauge we create 20 randomly gauge transformed copies of the gauge field configuration and apply the

Table 1: Parameters of configurations.

2.60	28^4	50	20

Simulated Annealing algorithm to fix gauges. We use in calculations that copy which correspond to the maximal value of the gauge fixing functional. To fix the indirect maximal center gauge from configuration fixed to maximally Abelian gauge and to fix the Z(2) degrees of freedom one gauge copy is enough to work with our accuracy. We work at various lattice spacings to check the existence of the continuum limit. The parameters of our gauge field configurations are listed in Table . To fix the physical scale we use the string tension in lattice units [14], $\sqrt{\sigma} = 440\, MeV$.
